Chapter 11 Chemical Bonding II: Valence Bond and Molecular Orbital Theories

We will start by continuing the Localized Electron Model of bonding (better known as "Valence Bond Theory")

We will study "hybrid orbitals", which just formalize the electron groups (or "featureless blobs" as I sometimes call them) of VSEPR.

 \triangleright It's like putting uniforms on the soldiers of a ragtag army and giving them ranks and titles.

Localized Electron Model (Valence Bond Theory) and VSEPR works well in predicting molecular geometries **Hybrid orbitals**

Localized Electron Model (Valence Bond Theory) and

VSEPR works well in predicting molecular geometries

• But ordinary atomic orbitals (s and p) <u>do not!</u>

• They would give the <u>wrong</u> bond angles and

- But ordinary atomic orbitals (s and p) do not!
-

 \triangleright No predicted angle between the spherical s-orbitals and the any of the p-orbitals \triangleright Predicted angle between p-orbitals is 90^o

Bottom line:

Atomic orbitals in the valence shell don't seem to survive bond-making!

- VSEPR works by treating electron pairs as indistinguishable "blobs"
- We can obtain indistinguishable atomic orbitals by mixing pure atomic orbitals: hybridization

• It's a "mathematically polite" way of getting our "blobs" of VSEPR

When an atom starts bonding, its original atomic orbitals are mixed (hybridized) in such a way that minimizes repulsion between electron pairs in skeletal bonds as well as lone pairs.

 \triangleright To achieve the same result predicted by VSEPR

Skeletal bonding pairs and the lone pairs have the same hybridization.

^{Hybrid orbitals}
Number of electron groups in Lewis structure
(no. of <u>skeletal bonds and lone pairs</u>) (no. of skeletal bonds and lone pairs)

Number of hybrid orbitals needed

What is a skeletal bond?

The first bond that forms between two atoms

The first bond in a double or triple bond

 \triangleright Second and third bonds are not skeletal (so, not made from hybrid orbitals)

How many hybrid orbitals does an atom need? Same as "electron groups" we counted in VSEPR. Count the skeletal bonds and lone pairs around it

How many hybrid orbitals does each O in $CO₂$ need?

1 skeletal bond 2 lone pairs \Rightarrow 1+2 = 3

$$
SO = C = \bigcap_{\text{Skeletal bond}} \mathcal{C} \cdot \sum_{\text{none pairs}}
$$

How many hybrid orbitals does N in $NH₃$ need?

3 skeletal bonds 1 lone pair \Rightarrow 3+1 = 4

How about the hydrogens?

They don't hybridize their orbitals. They keep their pure atomic 1s orbitals.

sp $1 + 1 = 2$ orbitals sp Hybridization Two electron groups on the atom: $\log \frac{p}{p}$
 $\log \frac{p}{p}$
 $\log \frac{p}{p}$
 $\log \frac{p}{p}$ $\frac{sp}{sc}=0$: sp $\begin{array}{c}\n\mathsf{By} \\

What if the central atom exceeds the octet?

- We once thought d-orbitals from the lower shell added into hybridization when there are more than 4 groups **What if the central atom exceeds the octet?**
• We once thought *d*-orbitals from the lower shell added
into hybridization when there are more than 4 groups
• But now it's just <u>pretense</u> in General Chemistry only
So, pret
-

So, pretend like …

- **d**-orbitals from the lower shell are "promoted" to participate in bonding
- They are added to the mix (hybridization) along with s and **p** orbitals.
- When d-orbitals are involved, we already have one s and three \boldsymbol{p} orbitals in the mix **•** They are added to the mix (hybridization) along with **s**

• They are added to the mix (hybridization) along with **s**

• When *d*-orbitals are involved, we already have one *s* and

three *p* orbitals in the mix

- electron groups needed

So, if we are not recruiting the d orbitals of the lower shell, how is it that the central atom can seem to have 5 or 6 electron groups, like we saw in VSEPR?

There is a reasonable way to describe those situations with resonance in unconventional Lewis structures involving ionic bonds, but we're not going to do that.

General Chemistry curriculum nationwide has not yet mustered the boldness to discard what's wrong and replace it with something that's not that hard to explain. I might start including it, but not yet.

dsp³ Hybridization Pretend hybridization #1

- Because 5 electron groups are needed
- Combination of one d, one s, and three p orbitals.
- Because 5 electron groups are needed
• Combination of **one** *d***, one** *s***, and three** *p* **orbitals.
• Gives a trigonal bipyramidal arrangement of 5
equivalent hybrid orbitals.** equivalent hybrid orbitals.

Consider the Lewis structure for PCI_{5}

What is the shape of the molecule? trigonal bipyramidal What are the ideal bond angles? 90° and 120° What is the hybridization of P? $dsp³$

The Orbitals Used to Form the Bonds in PCI₅

Notice how the sigma bonds are formed by head-to-head overlap of hybrid orbitals on P and Cl

> The central P atom is $dsp³$ hybridized

Cl atoms each have just one skeletal bond and three lone pairs, all sp^3 hybridized. But the **hybridization of** peripheral atoms doesn't affect the geometry around the central atom.

d²sp³ Hybridization Pretend hybridization #2

- Because 6 electron groups are needed
- Combination of two d , one s, and three p orbitals.
- Gives an octahedral arrangement of 6 equivalent hybrid orbitals.

Consider the Lewis structure for XeF_4 . .

What is the shape of the molecule? square planar What are the ideal bond angles? 90° and 180° What is the hybridization of Xe? d²sp³

How is the Xenon Atom in XeF_4 Hybridized?

Sigma (σ) Bond

- Skeletal bonds are called "sigma" bonds.
- Sigma bonds are formed by orbitals approaching and overlapping each other head-on. • Skeletal bonds are called "sigma" bonds.
• Sigma bonds are formed by orbitals approaching and
overlapping each other <u>head-on</u>.
• Two hybrid orbitals, or a hybrid orbital and an s-
orbital, or two s-orbitals
• The result
	- \triangleright Two hybrid orbitals, or a hybrid orbital and an sorbital, or two s-orbitals
- cylindrical symmetry.

Acts like an axle

• That means the bond shows no resistance to rotation around a line that lies along its length.

Pi (π) Bond

- The "leftover" p-orbitals that are not used in forming hybrid orbitals are used in making the "extra" carbon-carbon pi bond bonds we saw in Lewis structures.
	- \triangleright The 2nd bond in a **double** bond

 \triangleright The 2nd and 3rd bonds in a triple bond
Carbon-carbon sigma bond

- Those extra bonds form only after the atoms are brought $\frac{5}{3}$ together by the formation of the skeletal bonds made by hybrid orbitals. **hybrid** orbitals are used in making the "extra" carbon pibond

bonds we saw in Lewis structures.
 \triangleright The 2nd bond in a **double** bond
 \triangleright The 2nd and 3rd bonds in a **triple** bond

Those extra bonds form only
- The "extra" π bonds are formed alongside a skeletal bond.
- They don't form without a skeletal bond to bring the p-

- The pure p-orbitals are perpendicular to the hybrid orbitals.
- This causes the two lobes of the p-orbitals on the two atoms to stick out perpendicular to the skeletal sigma bond between them.
- Those p-orbitals on the two atoms align and form a "sideways" bond where the lobes of the p-orbitals merge to form a π (pi) bond. H

Pi (π) Bond vs sigma (σ) bond

© Arno Papazyan

Pi (π) Bond

sp2

The Orbitals for CO₂

- The two pi bonds are on perpendicular planes.
- If one is on the plane of this page, the "lobes" of the other are sticking into and out of the page.

Pi bonds don't allow rotation

- Since a π bond relies on the alignment of the p-orbitals on two atoms, rotation around the skeletal bond would mean breaking the π bond.
- That means π bonds prevent rotation around the skeletal bond over which they formed.

 π bond

• Breaking a pi bond would require too much energy

Exercise:

Draw the Lewis structure for HCN.

Show all bonds between atoms.

Label each bond as σ or π .

Which hybrid orbitals are used?

Exercise:

Determine the ideal bond angle(s) and the hybridization (real or pretend) of the central atom for each of the following molecules:

 $NH₃$ $SO₂$ $KrF₂$ $CO₂$ $|Cl₅$

The Molecular Orbital (MO) model of bonding The Molecular Orbital (MO) model of bondin
i.e. "the other model" of bonding
Electrons are assumed to occupy orbitals ju

- Electrons are assumed to occupy orbitals just like in atoms (2 e⁻ per orbital)
	- \triangleright But the orbitals extend over the entire molecule
- Formed from **pure** atomic orbitals like s and p \triangleright No hybrid orbitals in this picture!
- Atomic orbitals are replaced by molecular orbitals (MOs)
- Unlike the localized electron model, as well as bonds, it can also produce anti-bonds!
- Molecular electron configurations can be written in much the same way as atomic electron configurations.
- Each molecular orbital can hold 2 electrons with opposite spins.
- The number of orbitals is conserved.

The total number of atomic orbitals coming from different atoms is equal to the number of molecular orbitals created
Sigma (σ) molecular orbitals (MOs)

- Same shape and name as sigma (s) bonds
- The electron density of σ molecular orbitals is centered along the line passing through the two nuclei.
	- \triangleright It has the same "symmetry" as a stick (or a cigar, or an egg)
	- \triangleright If you spin it along its length, you won't see a change.
- Formed by "head-on" approach of atomic orbitals
- If you spin it along its length, you won't see a
change.
• Formed by "head-on" approach of atomic orbitals
• Spherical s <u>atomic</u> orbitals have no choice but approach
each other head-on and form sigma <u>molecular</u> orbital Formed by "head-on" approach of atomic orbitals

Spherical state on and form sigma molecular orbitals
reach other head-on and form sigma molecular orbitals

Sigma (σ) molecular orbitals (MOs)

We will first use the case of **sigma** molecular orbitals formed by s atomic orbitals to talk about "bonding" and "anti-bonding" molecular orbitals

Example:

Combination of Hydrogen 1s Atomic Orbitals to form MOs

https://cnx.org/resources/92f991702d0b48e34361c055884b247df2391425/CNX_Chem_08_04_ssigma.jpg

Again, the number of orbitals are conserved

Remember?

When we considered the hybrid atomic orbitals, the number of pure atomic orbitals going into the mix was equal to the number of hybrid atomic orbitals created.

Same here:

Two atomic orbitals create two molecular orbitals.

of atomic orbitals used $=$ # of MOs created

We will consider only the MOs formed by valence shell atomic orbitals. MOs made by core orbitals don't contribute significantly to bonding and chemistry.

Also, we consider only the molecular orbitals formed by We will consider only the MOs formed by <u>valence shell</u>
 atomic orbitals. MOs made by core orbitals don't

contribute significantly to bonding and chemistry.

Also, we consider only the molecular orbitals formed by

atom resulting MO would be essentially the same as the atomic orbital with the much lower energy, and not be useful as a "molecular orbital" description. atomic orbitals of similar (or same) energy; otherwise the
resulting MO would be essentially the same as the atomic
orbital with the much lower energy, and not be useful as a
"molecular orbital" description.
We will mostly

diatomic species, where MOs are formed by valence orbitals of equal energy, coming from each atom.

Energies of MOs:

- Anti-bonding MO > parent atomic orbitals
	- Bonding MO < parent atomic orbitals

bad! Anti-bonding MO > parent atomic orbitals
Bonding MO < parent atomic orbitals
Antibonding molecular orbital: higher in energy bad! Antibonding molecular orbital: higher in energy bad! $\overrightarrow{\text{two}}$
Bonding molecular orbital: lower in energy good

lower in energy good

Molecular Orbital Theory

MO Energy-Level Diagram for the H₂ Molecule

1s orbital of hydrogen A and 1s orbital of hydrogen B disappear, and form two molecular orbitals:

- \triangleright One with lower energy (bonding)
- \triangleright One with higher energy (anti-bonding)

decreased electron density between nuclei!

The molecular orbital model produces electron distributions and energies that agree with our basic ideas of bonding.

The labels on molecular orbitals indicate their symmetry (shape), and whether they are bonding or antibonding.

 \triangleright "Sigma" (σ) refers to the cylindrical/egg-shaped symmetry

This corresponds to the sigma bonds we discussed earlier.

 \triangleright We can't see a change if we spin the object along its length

Bond Order

- Higher bond order means greater bond strength.
- **Bonding** electrons make a bond stronger
- Antibonding electrons make a bond weaker
- It's the excess (net) bonding electrons that gives the bond its strength
- Two net bonding electrons correspond to a "bonding" pair" in one bond in the Lewis structures
- We can have fractional bond order (0.5, or 1.5, or 2.5) in the MO model

Bond order =
$$
\frac{\text{\# of bonding e}^- - \text{\# of antibonding e}^-}{2}
$$

Example: H₂

Molecular Orbital Theory – Bond order

Molecular Orbital Theory – Bond order

Example: $H_2^ -$ – $-$ – $-$ – $-$

 $2 - 1 - 1$ Bond Order = $\frac{2-1}{2}$ = $\frac{1}{2}$

1 Putting an extra electron on 2 H₂ makes the bond weaker!

Populating molecular orbitals

There is no good reason to keep writing the atomic orbitals, once we learn the energy order of the molecular orbitals formed by the valence orbitals of the atoms.

We then simply populate the MOs with the valence electrons in the order of increasing energy, from lower to higher.

The number of electrons in those MOs is the total number of valence electrons brought by the individual atoms, minus the charge on the species.

Example: $H_2^ -$ – $-$ – $-$ – $-$

We just populate molecular orbitals with the valence electrons. **Example:** H_2^-

e just populate molecular orbitals with the valence

ectrons.
 H_{charge}

has 3 valence electrons: $(2)(1) - (-1) = 3$

 H_2 ⁻ has 3 valence electrons:

$$
\begin{array}{c}\n\text{H} & \text{charge} \\
(2)(1) - (-1) = 3\n\end{array}
$$

Easy enough to list and order the MOs when we only have s-orbitals making molecular orbitals

Sigma and Pi orbitals

Sigma (σ) MO (when it is the "bonding" kind) corresponds to the σ bond we created using head-on overlap of hybrid atomic orbitals.

- \triangleright But no hybrid orbitals here!
- \triangleright Just pure atomic orbitals forming MOs.

Pi (π **) MO** (when it is the "<u>bonding</u>" kind) corresponds to the π bond we created using sideways overlap of the atomic pure p-orbitals.

Expected energy diagram for Molecular Orbitals

 π orbitals from the sideways-overlap of p-orbitals are expected to have smaller "reward" (lowering of energy) and "penalty" (raising of energy) for being bonding and "anti-bonding" than the corresponding σ orbitals

But … The expected energy diagram for MOs can predict the magnetism of dimers made of F, O, Ne only! Molecular Orbital Theory -- Energy Diagrams

am for MOs can predict

f E O No only!

It fails for any dimer that has Li, Be, B, C, N!

That's because, for the first 5 elements in a period, the actual MO energy diagram has an "unexpected" switch in the energy order!

The expected energy diagram places the electrons in the wrong orbitals and gets the pairing of electron spins wrong!

Quick reminder

Paramagnetism:

- Substance is attracted to a magnetic field
- One or more unpaired electrons

Diamagnetism:

- Substance is repelled by a magnetic field
- All electrons paired

Don't worry if you don't follow this.

For 2^{nd} period atoms other than O, F, Ne:

Lower energy σ_{2s} and σ_{2s} ^{*} * orbitals, together, mix with both Molecular Orbital Theory – Energy Diagrams

Pr than O, F, Ne:

Lower energy σ_{2s} and σ_{2s}^*

orbitals, together, mix with both

of the higher energy σ_{2p} and σ_{2p}^*

orbitals * orbitals

and are replaced with even higher-energy σ_{2p} and σ_{2p}^* , and even lower energy σ_{2s} and σ_{2s} ^{*} * orbitals

when at least one of the atoms is Li, Be, B, C, N © Arno Papazyan

Don't worry if you don't follow this.

Why don't O, F, Ne have the "switched" diagram?

O, F, Ne are at the end of the 2nd period.

The increasing nuclear charge affects the 2s electrons (and the σ_{2s} MOs they make) more than the 2p electrons (and the σ_{2p} MOs they make) because 2s electrons are closer to the nucleus.

When the energy levels of the σ_{2s} and σ_{2p} MOs are less similar, their interaction is less relevant.

The modification of the σ_{2s} and σ_{2p} energy levels is less.

The energy order of the MOs is as expected.

"Expected" Diagram

Applies only to O, F

*
